

# CrystalFramer: Rethinking the role of frames for SE(3)-invariant crystal structure modeling

**TL;DR:** To make a GNN invariant to rotations, let's standardize the orientations of local atomic environments represented by internal self-attention weights!

## Frame-based SE(3)-invariant crystal structure modeling

The key to modeling crystal structures lies in learning **SE(3)-invariant (i.e., rotation & translation invariant) representations.**

💡 Why not normalize the orientation of the input structure?

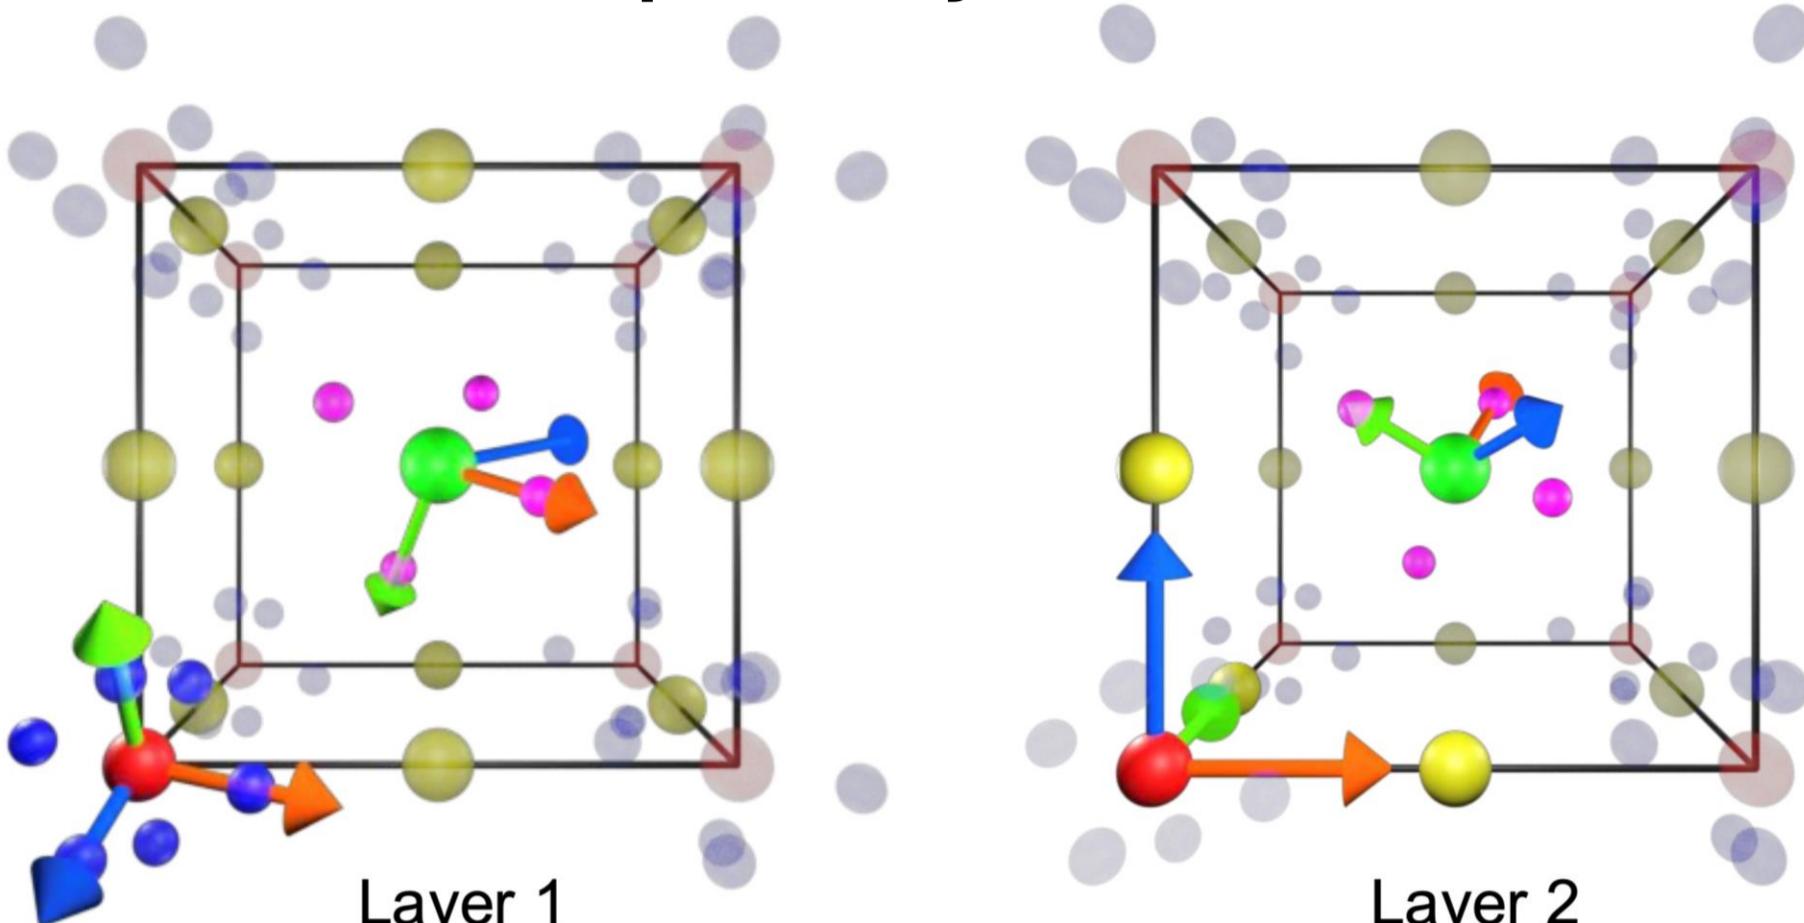

That's the “frame” (i.e., structure-aligned coordinate system)

Ex 1) PCA for the positions of atoms in a unit cell (PCA frame)

Ex 2) Lattice vectors of a unit cell (lattice frame)

- Can use richer information than interatomic distances
- No restriction on the network architectures
- **Is it enough to just align with the structure?**
- **Is there no need to adapt the frame based on the task?**

## Proposed dynamic frames

The fundamental role of the frame is to effectively incorporate **relative positional information** into the message-passing layers for **modeling interatomic interactions**:

$$x'_i = \sum_j w_{ij} f_{i \leftarrow j}(x_i, x_j, r_{ij})$$

💡 Let's consider a **frame aligned with the interatomic interactions** rather than with the structure itself.

## Dynamic frames: attention-based local frames

Suppose a message-passing layer in a general form:  $x'_i = \sum_j w_{ij} f_{i \leftarrow j}$ .

Interaction weights  $w_{ij}$  can be interpreted as a “mask” representing the local environment of the structure viewed from target atom  $i$ .

### Weighted PCA frame

For each atom  $i$ , compute the weighted covariance matrix of the direction vectors  $\bar{r}_{ij}$  pointing toward the surrounding atoms  $j$ .

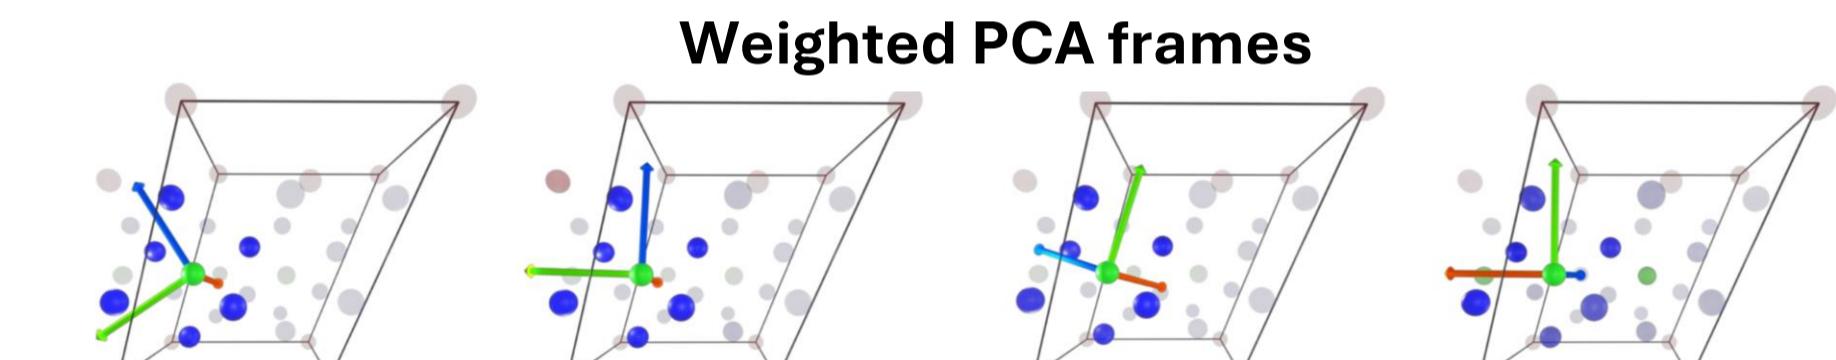

$$\Sigma_i = \sum_j w_{ij} \bar{r}_{ij} \bar{r}_{ij}^T$$

Set the orthonormal eigenvectors  $[e_1, e_2, e_3]$  of the matrix as the three axes of the frame.

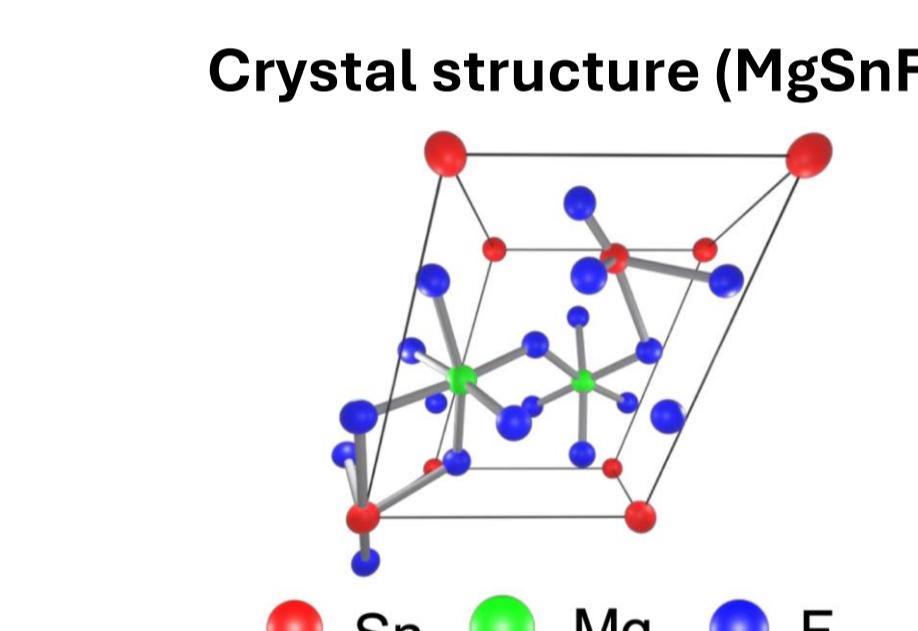

### Max frame

#### (Weight-sorted selection & orthogonalization)

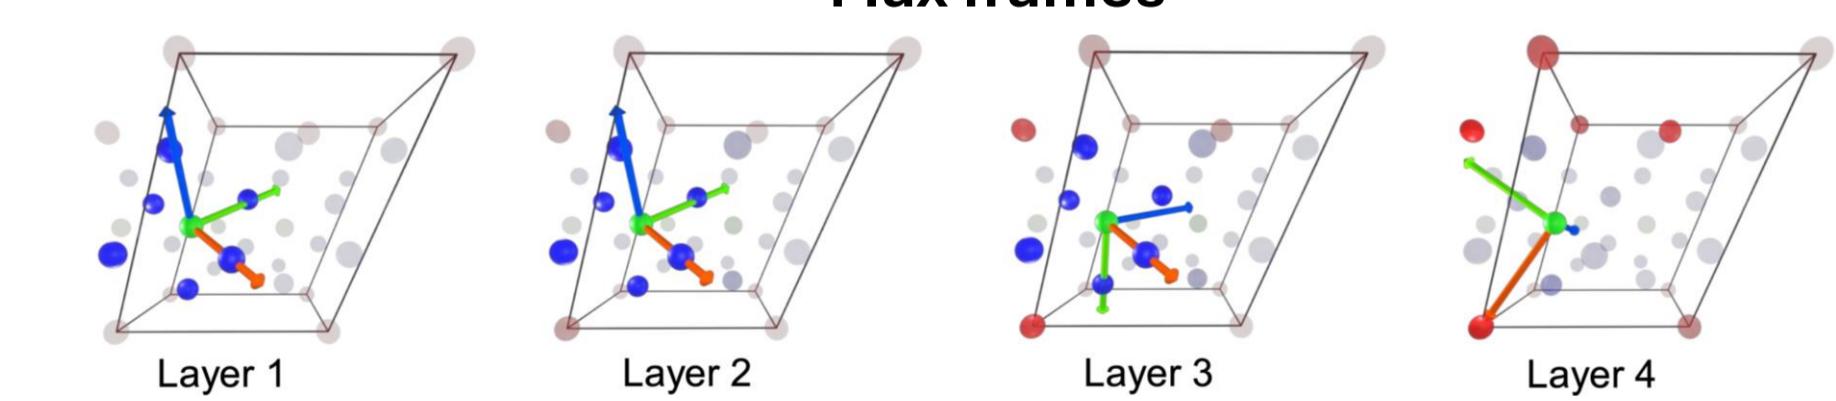

1. Set the first axis  $e_1$  to the direction  $\bar{r}_{ij}$  pointing toward the atom  $j$  with the highest weight  $w_{ij}$ .
2. To ensure diversity, select the direction  $\bar{r}_{ij}$  for the second axis candidate  $\hat{e}_2$  by maximizing the adjusted weight  $(1 - |e_1 \cdot \bar{r}_{ij}|)w_{ij}$ , which penalizes alignment with  $e_1$ .
3. Apply Gram-Schmidt orthogonalization to obtain  $e_2 = \hat{e}_2 - (e_1 \cdot \hat{e}_2)e_1$ .
4. Set  $e_3 = e_1 \times e_2$  to form a right-handed orthonormal system.

- ✓ Incorporating dynamic frame-based edge features substantially enhances the prediction performance.
- ✓ High model efficiency with only a small increase in parameters compared to the baseline Crystalformer.

The default ver encodes an angle into a 64-D vector using 64 Gaussian basis functions, while the lightweight ver uses a 16-D vec.
